Mean Flow Steepening in Internal Gravity Wave Breaking

Group Meeting Presentation

Yubo Su

Nov 30, 2018

Background

Problem Setup

- 2D plane parallel atmosphere, continuous train IGW from below.
- Equations to filter sound waves (actually surprisingly contentious):

$$\vec{\nabla}\cdot\vec{u} = 0, \tag{1}$$

$$\frac{\partial \rho_1}{\partial t} - \frac{u_{1z}\rho_0}{H} + \vec{u}\cdot\vec{\nabla}\rho_1 = [-\Gamma(z) + \mathfrak{D}]\rho_1 + \left\{F e^{-\frac{(z-z_0)^2}{2\sigma^2}} \cos(k_x x - \omega t)\right\}, \tag{2}$$

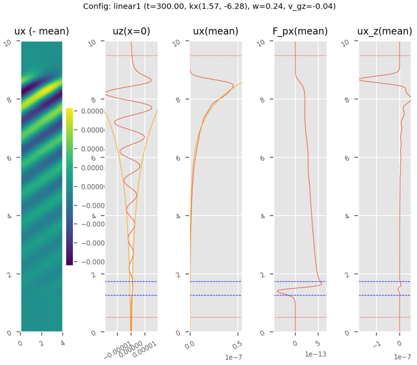
$$\frac{\partial \vec{u}}{\partial t} + \left(\vec{u}\cdot\vec{\nabla}\right)\vec{u} + \frac{\vec{\nabla}P_1}{\rho_0} + \frac{\rho_1 \vec{g}}{\rho_0} - \frac{\vec{\nabla}P_1}{\rho_0}\rho_1 = [-\Gamma(z) + \mathfrak{D}]\vec{u} \tag{3}$$

- $\Gamma(z) \propto 2 + \tanh\left(\frac{z - z_H}{w}\right) + \tanh\left(\frac{z_b - z}{w}\right), \mathfrak{D} \sim \nabla^k$. ([] numerical, {} forcing).
- If $\frac{\mathrm{d}\ln\rho_0}{\mathrm{d}z} = H$ scale height $\gg$ domain of simulation, can use $\rho_0(z) = \rho_0$, *Boussinesq approximation*. Else, ~ *anelastic*.

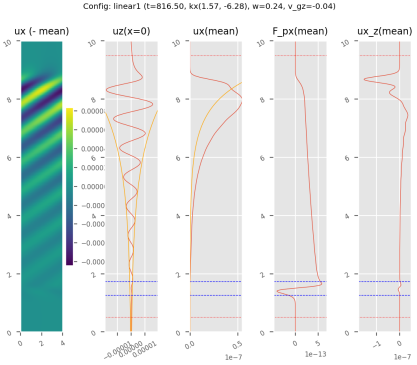
- Perturbation $(\vec{u}, \rho_1, P_1)$ carries average horizontal momentum flux $\langle F_{p,x} \rangle_x = \langle \rho u_x u_z \rangle$.
- Induces mean flow
$$\langle u_x \rangle_x \equiv \bar{U}_x(z) \neq 0 = \frac{\langle u_x u_z \rangle_x}{c_{g,z}}. \tag{4}$$
- Critical layer (equivalent to corotation resonance in other systems): where Doppler-shifted frequency (in fluid rest frame) $\omega \Rightarrow \omega - k_x \bar{U}_x = 0$.
- Since $\vec{u} \propto e^{z/2H}$, so $\bar{U}_x \propto e^{z/H}$, $\exists z_c : \omega - k_x \bar{U}_x(z_c) = 0$.

- Since critical layers almost always induce full absorption (recall, $\propto \exp\left[-\pi\sqrt{\mathrm{Ri}^2 - \frac{1}{4}}\right], \mathrm{Ri} = \frac{N}{\bar{U}_x'}$), hypothesis:
  - $\vec{u}_1$ is excited, induces $\bar{U}_x$ mean flow.
  - Once $\bar{U}_x$ satisfies critical layer criterion, $F_{p,x}$ is fully absorbed.
  - Horizontal momentum goes into spinning up more fluid up to $\bar{U}_{x,crit} = \frac{\omega}{k_x}$.
  - Thus, critical layer should propagate down.
- Exactly *quasi-biennial oscillation* theory (Lindzen 1980, 1982), assume critical layer breaks down eventually.
- Already different from naive "goes nonlinear and deposits locally" theory!

- Permit $z \in [0H, 10H]$, full $\rho_0 \propto e^{-z/H}$, allow $\vec{u} \propto e^{z/2H}$ to source growing mean flow.
- Low-Amplitude ($k_z \xi_z \ll 1$ everywhere). Orange = analytical solution.



(a) Early Low-A



(b) Later Low-A

Simulations

Large Anelastic, Low-Amplitude

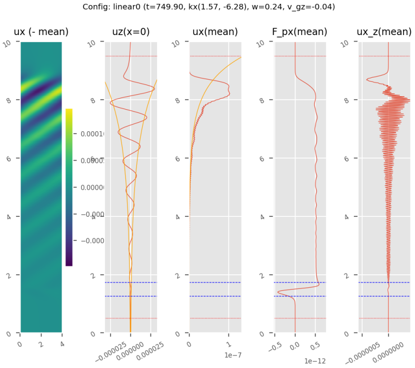


Figure: Low-Amplitude, nearly zero viscosity.

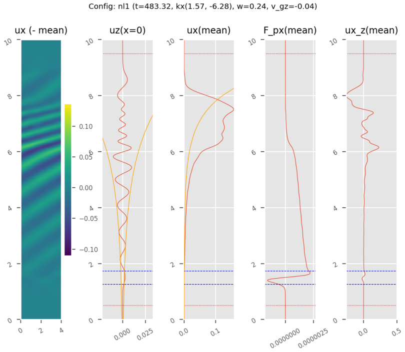
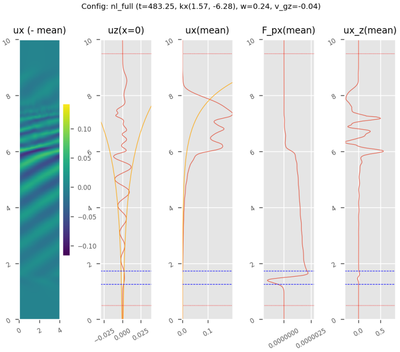
Simulations

Large Anelastic, High-Amplitude

- Note steepening region ($N = 1$, so $\frac{\partial \bar{U}_x}{\partial z} = \mathrm{Ri}^{-1}$).

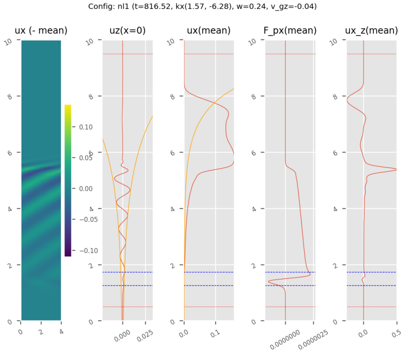


(a) Lower-res.

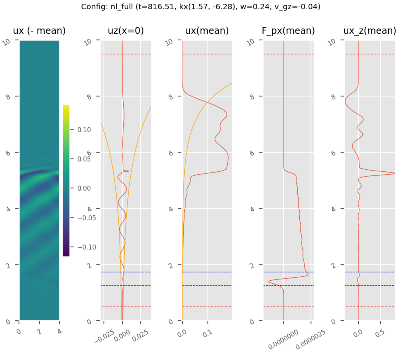


(b) Double N_z.

- Later



(a) Lower-res.



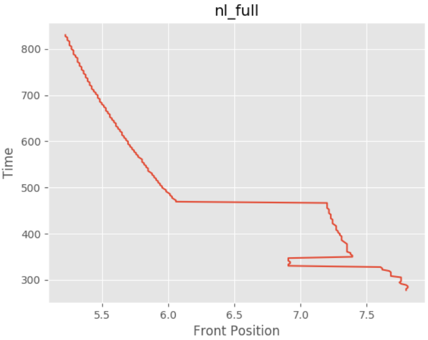
(b) Double N_z.

- While damping layers pump up $\bar{U}_x$, ran on higher amplitude, seems not to be damping layer.
- Would expect reflections, but *viscously limited*?
    - Indeed, $\mathrm{Ri}^{-1} \sim \left|\vec{k}\right| d$ where d is the width of the spinup layer, then $\nu \rho_0 \frac{\bar{U}_{x,c}}{d^2} \sim \frac{F_{p,x}}{d}$.
- Matching $F_{p,x} = \langle \rho_0 u_x u_z \rangle$ with spinning up mass $F_{p,x} = u_{front} \rho_0 \bar{U}_{x,crit}$ lets us predict u_{front}, next page.

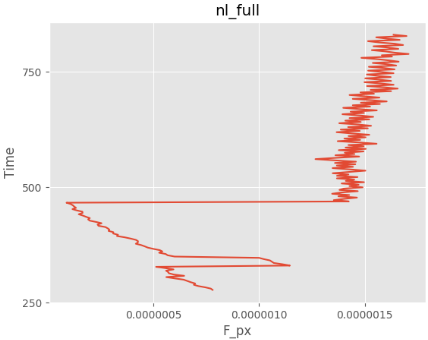
Simulations

Large Anelastic, Predicting u_{front}

- Front position is $z_f = \mathrm{argmax}_z \frac{\mathrm{d}\bar{U}_x}{\mathrm{d}z}$, while $F_{p,x} = 2F_{p,x}(z_f)$ ($\sim$ halfway in front).
- Predicts $u_{front} = \frac{F_{p,x}}{\rho_0(z)\bar{U}_{x,c}} \approx 2.2 \times 10^{-3} NH$ (using $z \approx 5.5H$), or $2H/3$ in $300N$. Pretty close, seems to imply perfect absorption.



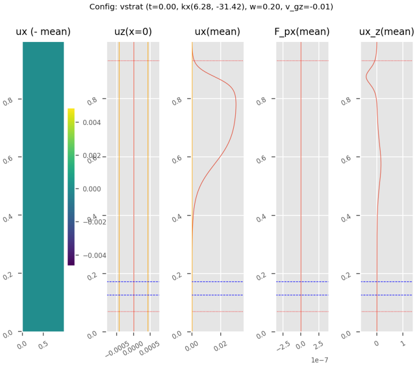
(a) Front Position. Slight exponential.

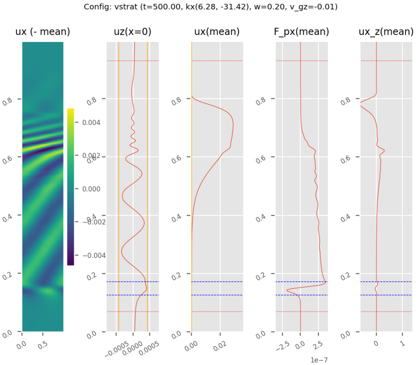


(b) $F_{p,x} = \langle \rho_0 u_x u_z \rangle_x$.

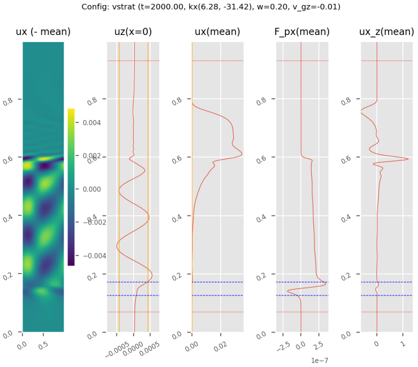
Simulations
Local Boussinesq

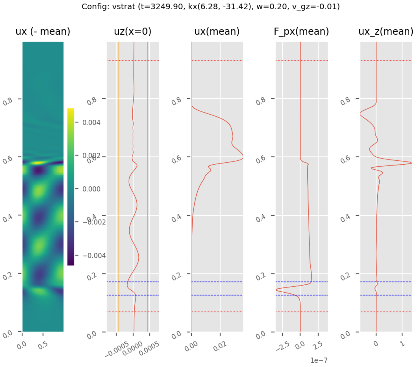
- Go to Boussinesq, "zoom in." Use $\mathfrak{D} = \nabla^6$ regularization. Set up initial mean flow $\bar{U}_x(z)$ such that $\max_z \bar{U}_x(z) = \bar{U}_{x,c}$.
- Reflection indeed develops!



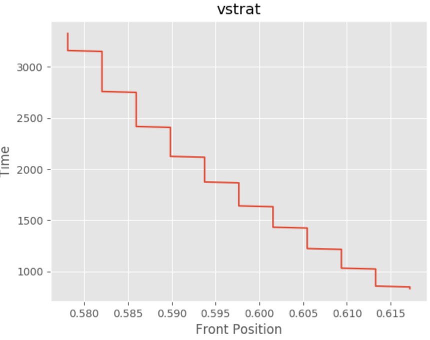


- Expect Kelvin-Helmholtz instability to develop; resolution-limit?
- Not viscosity-limited: $\nu^{(6)}\rho_0 \frac{\bar{U}_{x,c}}{d^6} \ll \frac{F_{p,x}}{d}$!

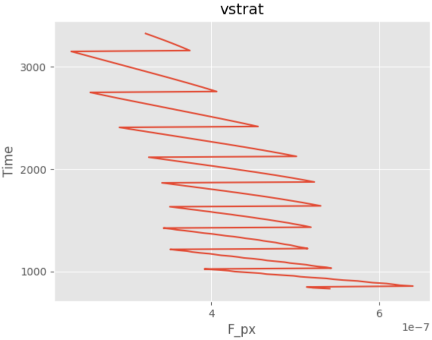




- Same as for anelastic, but predicts $u_{front} \approx \frac{4.5\times10^{-7}}{\rho_0 \bar{U}_{x,c}} \approx 1.4\times10^{-5}HN$ or $0.014H$ in $1000N$. $t \in [1000, 2000]$ accurate, $t \in [2000, 3000]$ less so.
- No front slowdown is expected since ρ_0 is constant in space, but is observed; could be explained by increasing reflectivity.



(a) Front Position. Slowing down.



(b) $F_{p,x}$.
